the “GALEX-Arecibo-SDSS Survey” (GASS)

Goal: Provide the first statistical sample of massive galaxies with homogeneously measured stellar and gas masses, to study their link with star formation and other global physical properties.

Project: 1000 galaxies with atomic gas measurements (Arecibo) and 350 with molecular gas (550 hours at IRAM 30m).

P.I.s: G. Kauffmann, D. Schiminovich, C. Kramer (B. Catinella & A. Saintonge)
the sample is selected purely on mass ($M^* > 10^{10} \, M_\odot$) and volume ($100 < D < 200 \, \text{Mpc}$)
MH2/M* is on average 6%, with little dependence on stellar mass or concentration index. The ratio never exceeds 20% within our sample.

There are thresholds in mu*, C and NUV-r above which the molecular gas quickly stops being detectable at the MH2/M*~2% level.
molecular gas in early-type galaxies

Above these thresholds (here NUV-r is shown), any significant cold gas found is in the atomic phase, not in the molecular phase. This conclusion is reinforced by the stacking of the CO non-detections.
the balance of atomic and molecular gas

On average, \( M_{\text{H}_2} = 0.3M_{\text{HI}} \) but huge galaxy-galaxy variations that do not correlate much with global physical parameters.
the balance between gas and star formation

Genzel et al. (2010)

\[ t_{\text{dep}}(H_2) = \frac{M_{H_2}}{SFR} \]

period of time over which star formation can be sustained at the current rate, assuming the system is closed

most previous studies find the molecular gas depletion time to be constant at ~1-2 Gyr for normal star-forming galaxies, both at low and high redshifts.
Within the COLD GASS sample, the molecular gas depletion time is found to vary with a large number of global parameters. The strongest dependencies are with quantities relating to star formation.

COLD GASS can find these trends, which were not seen in previous samples, because of the broader parameter spaces it covers (e.g. in $\mu^*$ and SSFR), being a complete mass-limited sample.
a metallicity effect on $X_{\text{CO}}$?

The molecular gas depletion time does not appear to depend on metallicity *within our mass range*. In the mass-metallicity plane, it is clear that variations in $t_{\text{dep}}$ happen along the mass axis, and not the Z axis.
a metallicity effect on $X_{\text{CO}}$?

No evidence for metallicity effects on $X_{\text{CO}}$ (within our sample of massive galaxies!)
The scatter and slope of the KS relation found previously using various compilations of galaxies is reproduced by the complete COLDGASS sample. But thanks to the size and homogeneity of the sample, we are starting to see some structure in the scatter about the relation.

Genzel et al. (2010):
y = 1.17x - 3.48
standard deviation: 0.32

COLD GASS:
y = 1.20x - 3.42,
standard deviation: 0.32

For example, here galaxies are color-coded by stellar mass, from low (blue) to high (red).
linking the various galaxy populations

at $z=0$, the depletion time decreases from the value of 1Gyr found in normal star-forming galaxies to the value of $<100$Myr found in major mergers (ULIRGs). The population of local LIRGs appears to extend the trend between these two extremes.

SSFR increases from $z=0$ to $z=2$ because gas fractions are much larger, but the depletion times shows little evolution.

data from: Leroy et al. (2009), Howell et al. (2010), da Cunha et al. (2010), Genzel et al. (2010), Hainline et al. (2010), Saintonge et al. (2011b)
explaining the depletion time variations

on average, the molecular gas depletion time is ~1.5 Gyr, but large galaxy-to-galaxy variations within our complete and representative sample of M*>10^{10} Msun galaxies, with values ranging from 300 Myr to ~10 Gyr.
explaining the depletion time variations

In the KS plane, Genzel+2010 and Daddi+2010 have shown that merging systems lie systematically offset from the main relation traced by normal star-forming galaxies.

\[
\log \Sigma_{\text{SFR}} \quad \text{[M}_\odot \text{ yr}^{-1} \text{ kpc}^{-2}] \\
\log \Sigma_{\text{H}_2} \quad \text{[M}_\odot \text{ pc}^{-2}] 
\]
can we explain the scatter within the normal population along these same lines? Since the galaxies with the strongest dynamical disturbances (major mergers) lie the farthest off the main KS relation, what about the galaxies with more minor disturbances?

indication in the COLD GASS sample that the galaxies with strong bars and marked lopsidedness then to lie on the short depletion time side of the relation, toward the branch traced by the major mergers.
explaining the depletion time variations

molecular gas depletion time

Bournaud (2011)
also Martig et al. (2009), Crocker et al. (2011)
- COLD GASS offers a complete view of the balance between HI, H\(_2\) and stars in massive galaxies.

- There are sharp thresholds in galaxy properties, above which any cold gas is found in the atomic phase.

- The molecular depletion timescale is not universal: varies from \(~500\)Myr to \(3\)Gyr in the mass range of \(10^{10}\) to \(10^{11.5}\) M\(_{\odot}\).

- The \(t_{\text{dep}}\)-sSFR relation extends smoothly from the normal COLD GASS galaxies to nearby LIRGs and ULIRGs.

- Normal galaxies at \(z=1,2\) are displaced from this plane, having longer depletion times at fixes sSFR, owing to their large gas fractions.

- At \(z=0\), \(t_{\text{dep}}\) variations among star forming disks can be explained in part by a range of dynamical processes.
